Abstract: Bile acid (BA) is *de novo* synthesized exclusively in the liver and has direct or indirect antimicrobial effects. On the other hand, the composition and size of the BA pool can be altered by intestinal microbiota via the biotransformation of primary BAs to secondary BAs, and subsequently regulate the nuclear farnesoid X receptor (FXR; NR1H4). The BA-activated FXR plays important roles in BA synthesis and metabolism, glucose and lipid metabolism, and even hepatic autophagy. BAs can also play a role in the interplays among intestinal microbes. In this review, we mainly discuss the interactions between BAs and intestinal microbiota and their roles in regulating host metabolism, and probably the autophagic signaling pathway.

Key words: Bile acid (BA), Farnesoid X receptor (FXR), Intestinal microbiota, Host metabolism, Autophagy
doi:10.1631/jzus.B1400327 **Document code:** A **CLC number:** S82

1 Introduction

Bile acid (BA) is biosynthesized *de novo* in hepatocytes, remained in cholecystis and further converted to secondary BA by intestinal microbiota (Ridlon *et al.*, 2006). BA contributes to the emulsification and solubilization of fats. In addition, it can regulate farnesoid X receptor (FXR; NR1H4) that not only alters the transcription levels of critical genes in BA synthesis, transportation, and metabolism (Makishima *et al.*, 1999), but is also involved in lipid, glucose, and energy metabolism (Zollner *et al.*, 2006; Nguyen and Bouscarel, 2008). Interestingly, FXR is also identified as inhibiting autophagy-related genes (*Atgs*) in the fed state (Lee *et al.*, 2014; Seok *et al.*,

2014). A large quantity of host and environmental factors can change the composition of intestinal microbes, such as lifestyle, diet, antibiotics, and the host's environment. In addition, more evidence has revealed that BA is also able to alter gut microbes via direct and indirect antimicrobial effects (Begley *et al.*, 2005), and even contribute to the survival of some BA-tolerant bacteria (Devkota *et al.*, 2012).

Currently, a growing body of research has highlighted that intestinal microbiota disorders can lead to varieties of diseases, for instance, obesity, colon cancer, and *Clostridium difficile* infection (CDI) (Hill and Artis, 2010; Kau *et al.*, 2011; Tremaroli and Backhed, 2012). In addition, accumulating evidence indicates that intestinal microbiota contributes to the biotransformation of primary BAs to secondary BAs and alters BA composition (Midtvedt, 1974), leading to the activation or inhibition of FXR (Hu *et al.*, 2014) and the subsequent alteration of BA pool size via two FXR-dependent feedback mechanisms of hepatic BA synthesis (Kim *et al.*, 2007). Taken together, BAs can affect the communal structure of intestinal microbes, in turn, intestinal microbes are able to alter BAs. The

cross-talk between BAs and intestinal microbes plays essential roles in host metabolism.

Interestingly, BAs play important roles in the interplay among intestinal microbes. For instance, fecal microbiota transplantation (FMT) can restore the intestinal microbiota and fecal BA composition in patients with recurrent CDI (Weingarden *et al.*, 2014). The spore germination of *C. difficile* can be stimulated by some primary BAs except for chenodeoxycholic acids (CDCAs) (Sorg and Sonenshein, 2008) or inhibited by secondary BAs such as lithocholic acids (LCAs) and ursodeoxycholic acids (UDCAs) (Sorg and Sonenshein, 2010), and FMT can restore gut microbes which can convert primary BAs to secondary BAs, thus inhibiting *C. difficile* spore germination. In this review, we mainly focus on the metabolism of BA, the interactions between BAs and intestinal microbiota, and the cross-talk between BAs and intestinal microbiota in regulating host metabolism, and probably autophagic signaling pathways.

2 Biosynthesis and enterohepatic circulation (EHC) of BAs

BA is an amphipathic molecule that is synthesized *de novo* exclusively in hepatocytes (Fig. 1) (Begley *et al.*, 2005). Several previous reviews have summarized in detail the biosynthesis of BA (Chiang, 2004; Lefebvre *et al.*, 2009; de Aguiar Vallim *et al.*, 2013). In brief, two BA biosynthetic pathways are present in the liver. One is the classic or neutral BA synthetic pathway in which cholesterol 7α -hydroxylase (CYP7A1) converts cholesterol into 7α -hydroxycholesterol. This first and rate-limiting hydroxylation step plays a vital role in BA synthesis (Myant and Mitropoulos, 1977). Then, 7α -hydroxycholesterol is catalyzed by sterol 12α -hydroxylase (CYP8B1) and sterol 27 -hydroxylase (CYP27A1) to generate cholic acid (CA) and CDCA (Bjorkhem, 1992). In human liver, CA and CDCA are predominant primary BAs. However, in rodent liver, CDCA can be converted into α/β -muricholic acid (α/β -MCA), which is also primary BA (Zhang *et al.*, 2014). The alternative BA synthetic pathway mainly leads to the synthesis of CDCA. The cholesterol side chain is oxidized by CYP27A1 and then the steroid ring is hydroxylated by oxysterol 7α -hydroxylase

(CYP7B1). Cholesterol is also converted to 24 -, 25 -, or 27 -hydroxycholesterols in other organs, such as the lung and brain, and these oxysterols are used for hepatic synthesis of BAs.

Fig. 1 Synthesis and EHC of BAs

This figure is modified from Li and Chiang (2013)

Before being secreted into the bile, primary BAs can conjugate with glycine or taurine under the catalysis of BA coenzyme A synthetase (BACS) and BA amino acid transferase (BAAT) to generate bile salts, which are transported to canaliculi and form bile through the bile salt export protein (BSEP; ABCB11). After a meal, dietary fat stimulates intestinal mucosa to secrete cholecystokinin, which can promote the contraction of the gallbladder, thus facilitating the secretion of bile salts into the small intestine. Most bile salts (95%) are re-absorbed by the intestine via the apical sodium-dependent bile acid transporter (ASBT) and the organic solute transporters (OST α/β), and then flow into the portal blood (Dawson *et al.*, 2005). The intestinal BA-binding protein (IBABP) contributes to the transportation of BAs across the ileal enterocytes. However, a mini-fraction of CAs, CDCAs, and MCAs are not re-absorbed. They are modified to generate deoxycholic acids (DCAs), LCAs, ursocholic acids (UCAs), and UDCAs in the human, and DCAs, UCAs, UDCAs, murideoxycholic acids (MDCAs), and hyodeoxycholic acids (HDCAs) in mice, which are all secondary BAs, under the catalysis of 7α -dehydroxylase in bacteria (Zhang *et al.*,

2014). Most LCAs are excreted into feces, their loss being compensated by *de novo* BA biosynthesis. Others return to hepatocytes and are sulfated before excretion to the gallbladder (Wang *et al.*, 2009). Meanwhile, DCAs are re-absorbed in the colon. The re-absorbed primary and secondary BAs return to hepatocytes via the transportation of (Na⁺)-dependent taurocholic acid co-transporting polypeptide (NTCP) and organic anion transporting polypeptide (OATP) to complete EHC (de Aguiar Vallim *et al.*, 2013).

BAs are potent detergents and contribute to the absorption and transportation of lipids, nutrients, and fat-soluble vitamins (Begley *et al.*, 2005). BAs also are identified to be natural ligands for FXR, which can be regulated by BA and subsequently modulate metabolic pathways (Houten *et al.*, 2006; Eloranta and Kullak-Ublick, 2008).

3 BAs as regulators of intestinal microbiota

The recent literature has suggested that BAs not only have direct antibacterial effects but also affect microbiota indirectly via nuclear receptors (Begley *et al.*, 2005; Inagaki *et al.*, 2006). However, some BA-tolerant microbes can thrive in the presence of BAs (Fig. 2a) (Devkota *et al.*, 2012).

3.1 Direct effects of BAs on bacteria

When BA-intolerant bacteria are exposed to BAs, cell membrane integrity can be altered and intracellular enzymes leak out, resulting in the inhibition of bacterial overgrowth (Noh and Gilliland, 1993; de Valdez *et al.*, 1997). High levels of BAs dissolve phospholipids and dissociate intrinsic membranous proteins, leading to the spillage of intracellular materials

Fig. 2 Interactions between BAs and gut microbes in host metabolism and probably in autophagy signaling pathways

(a) Interactions among gut microbes, BAs, and FXR. Gut microbes involve in the transformation of primary BAs into second BAs. BAs have direct and indirect antimicrobial effects, and even can favor the growth of BA-tolerant bacteria. BAs can activate or inhibit the expression of FXR, which in turn has profound effects on the synthesis and transportation of BAs. (b) Interactions among gut microbes, BAs, and FXR in host health. (c) Potential relationships between gut microbes and autophagy mediated by BAs. Interactions among gut microbes, BAs and FXR have been elucidated. The inhibition of hepatic autophagy by FXR-CREB complex has also been demonstrated. However, whether gut microbes can regulate autophagy via BAs and FXR pathways needs to be further investigated. (d) BAs as mediators among gut microbes. *C. scindens* can convert primary BAs (P.BAs) to secondary BAs (S.BAs). Primary BAs can stimulate *C. difficile* spores germination but secondary BAs can inhibit *C. difficile* spores germination

(Heuman *et al.*, 1996). Low concentrations of BAs can also affect the permeability and fluidity of cell membrane and change membrane characteristics (Noh and Gilliland, 1993). The antimicrobial potency of DCA is 10 times greater than that of CA (Kurdi *et al.*, 2006). Additionally, previous studies have shown that BAs may affect some microbial cells in other ways, such as inducing DNA damage, activating enzymes involved in DNA repair, and altering protein structure (Kandell and Bernstein, 1991; Bernstein *et al.*, 1999). A recent study of Cremers *et al.* (2014) revealed that bile salts have profound effects on many key proteins in bacteria through protein unfolding, aggregation and disulfide stress. Therefore, BAs are thought to have destructive effects on gut microbes except for some BA-tolerant bacteria.

3.2 Indirect effects of BAs on bacteria

Interestingly, oral BAs can activate FXR and inhibit the bacterial proliferation resulting from biliary obstruction in rodents, and then protect the ileum from microbial infection (Ding *et al.*, 1993; Lorenzo-Zúñiga *et al.*, 2003). Inagaki *et al.* (2006) showed that BA-activated FXR can induce the expression of genes, such as *Ang1*, *iNos*, and *Il18*, which are involved in enteroprotection. The products of these genes contribute to the inhibition of microbial overgrowth and mucosal damage. Furthermore, in cultured biliary epithelial cells, CDCA and UDCA are able to induce the expression of cathelicidin through FXR and vitamin D receptor. Cathelicidin is an antimicrobial peptide which acts against microbial invasion in the biliary epithelium and this may contribute to biliary tract sterility (D'Aldebert *et al.*, 2009). Taken together, BAs can affect microbiota via nuclear receptors indirectly.

3.3 Growth of BA-tolerant bacteria

However, the proliferation of some BA-tolerant microbes, such as *Bilophila wadsworthia*, *Escherichia coli*, and *Listeria monocytogenes*, can be facilitated by BAs, leading to the suppression of other symbiotic microbes (Hardison, 1978; Laue *et al.*, 1997; David *et al.*, 2014). Furthermore, some gut commensals can also tolerate BAs, such as some *Lactobacillus* and *Bifidobacterium* species expressing bile salt hydrolase (Begley *et al.*, 2005). Early studies observed the proliferation of *B. wadsworthia* in the

presence of BAs since sulphite in taurine-conjugated BAs can be used as a terminal electron acceptor (Hardison, 1978; Laue *et al.*, 1997). Another report revealed that sulfur-reducing bacteria (e.g. *B. wadsworthia*) thrive when interleukin-10-deficient (*Il10*^{-/-}) mice were fed with a milk-derived fat diet, because milk fat contributes to high levels of taurine-conjugated BAs and provides enough organic sulphur for sulfur-reducing bacteria. Moreover, adding taurocholic acid (T-CA) to a low-fat diet also contributes to the growth of *B. wadsworthia* in *Il10*^{-/-} mice (Devkota *et al.*, 2012). In addition, David *et al.* (2014) showed an increase of BA-tolerant microbes and a decrease of Firmicutes in volunteers taking the animal-based diet.

3.4 Complex relationships among dietary fat, BAs, and intestinal microbes

Research on the human diet has suggested that BA profiles may be changed from glycine to taurine-conjugation after feeding a “Western diet” (i.e. a high-fat diet) for a long time (Hardison, 1978). As described above, BAs are able to act as regulators of intestinal microbes. In this regard, a recent study demonstrated that a “Western diet” is capable of increasing Firmicutes, decreasing Bacteroidetes, and disturbing the ecological balance between the two predominant gut microbes (Murphy *et al.*, 2010). Accordingly, only gut microbes which possess high BA tolerance can survive when a diet supplemented with CA is administered (Islam *et al.*, 2011). A marked reduction in Bacteroidetes and an expansion in Firmicutes after CA intake were shown, resulting in an obvious expansion of BA 7 α -dehydroxylating species, which can produce secondary BAs. Therefore, BAs in the intestine have negative effects on Bacteroidetes and Actinobacteria, while they exert beneficial effects on Firmicutes, especially on BA 7 α -dehydroxylating species. Taken together, these studies have revealed complex relationships among dietary fat, BAs, and intestinal microbes.

4 Regulation of BA profiles by intestinal microbiota

It has been demonstrated that BA pool size and composition can regulate the structure of intestinal

microbiota. By contrast, mechanisms of disturbed intestinal microbiota affecting BA profiles have also been shown (Ridlon *et al.*, 2014). Previously, studies have revealed that intestinal microbiota has profound effects on BA profiles (Sayin *et al.*, 2013). Compared with conventional rats, germ-free (GF) rats fed with a diet supplemented with suitable cholesterol have more BAs in the bile; furthermore, levels of T-CAs are higher (Wostmann, 1973). Consistent with this, a recent study showed that T-CA, especially T- β -MCA, is the major BA in many host tissues (e.g. liver, kidney, and heart) of GF mice (Swann *et al.*, 2011). In addition, Vrieze *et al.* (2014) revealed that oral vancomycin caused a suppression of Firmicutes (mainly Gram-positive bacteria) and an expansion of Proteobacteria (mainly Gram-negative bacteria), resulting in reduced secondary BAs in feces and increased primary BAs in plasma. In sum, intestinal microbiota can affect BA pool size and composition via regulating the biotransformation, biosynthesis, and transportation of BA.

4.1 Biotransformation of BAs by intestinal microbiota

It has been elucidated that intestinal microbiota profoundly affects the biotransformation of BAs (Fig. 2a) via deconjugation, dehydrogenation, epimerization, and $7\alpha/\beta$ -dehydroxylation of primary BAs and generates secondary BAs (Ridlon *et al.*, 2006). Deconjugation is the process of fracturing the C-24 *N*-acyl amide of conjugated BA which links BA to glycine or taurine and generates unconjugated BA. A wide array of gut bacteria possess bacterial bile salt hydrolases (BSH) and bacterial hydroxysteroid dehydrogenases, which are involved in the deconjugation and dehydrogenation of bile salts, respectively, while only a minor population of gut bacteria in *Clostridium* clusters XI and XVIa, such as *C. sordellii*, *C. sordelliifell*, and *C. scindens*, which belong to the Firmicutes phylum, possess $7\alpha/\beta$ -dehydroxylase and catalyze the dehydrogenation reaction of BA (Midtvedt, 1974; Hayakawa, 1982; Doerner *et al.*, 1997; Ridlon *et al.*, 2006). A recent study revealed a clear elevation of *Clostridium* clusters XI and XVIa in high-fat-diet mice, and *Clostridium* cluster XI contained a sole species resembling *C. sordellii* and accounted for more than 12% of the fecal microbiota (Yoshimoto *et al.*, 2013).

BA profiles can be altered by intestinal microbes owing to their different BA metabolic enzymes. Li *et al.* (2013) showed that when mice were treated with tempol, an antioxidant which can reduce *Lactobacillus* and inhibit their BSH activity, a diminution of the Firmicutes:Bacteroidetes ratio, a decrease of secondary BAs, and an increase of T- β -MCA were observed. As noted in the study of Sayin *et al.* (2013), secondary BAs are potent FXR agonists but T- β -MCA is a FXR antagonist. Thus tempol-treated mice have an enlarged BA pool size attributed to the inhibition of FXR signaling, and the decrease of secondary BAs is mainly caused by the decline of *Clostridium* clusters XI and XVIa, which are involved in the dehydrogenation of BAs (Li *et al.*, 2013). Notably, high accumulation of secondary BAs in the EHC system of individuals may result in diseases, such as colon cancers and gallstones (McGarr *et al.*, 2005).

4.2 Biosynthesis of BAs regulated by intestinal microbiota

BA synthesis is regulated through BA feedback mechanisms which are involved in the expression of BA activated-FXR (Fig. 2a). The regulation of FXR is attributed to the size and composition of the BA pool (Russell, 2003). As summarized by Hu *et al.* (2014) recently, CA, CDCA, DCA, and LCA are FXR-agonistic, whereas α/β -MCA and UDCA are FXR-antagonistic. They observed an increase in BA synthesis and an enlarged BA pool in *Cyp8b1*^{-/-} mice, ampicillin (AMP)-treated mice, and GF mice, which was attributed to the expansion of α/β -MCA and UDCA and the reduction of DCA. At present, FXR is identified as modulating the expression of CYP7A1, which is a key enzyme in limiting hepatic BA synthesis through two mechanisms. In hepatocytes, CYP7A1 is inhibited by BA via an FXR/SHP/LRH-1 mechanism. In enterocytes, CYP7A1 is inhibited via the FXR/FGF15/FGFR4 mechanism (Kim *et al.*, 2007). Once activated by BA, hepatic FXR triggers a small heterodimer partner (SHP) to suppress the transcriptional level of liver-relaxin homolog-1 (LRH-1), thus suppressing CYP7A1 transcription. In addition, SHP can combine with hepatocyte nuclear factor 4 α to inhibit CYP7A1 and CYP8B1 transcription (Goodwin *et al.*, 2000). Simultaneously, BA-activated FXR expressed in the gut also contributes to BA homeostasis. Intestinal FXR in mouse can induce

fibroblast growth factor (FGF) 15 that can activate fibroblast growth factor receptor 4 (FGFR4) to suppress CYP7A1, thus inhibiting hepatic BA synthesis (Holt *et al.*, 2003).

As mentioned above, gut microbes can modulate the BA pool and composition, which in turn significantly affects the BA profiles. Administration of antibiotic, such as AMP, bacitracin, streptomycin, and neomycin, can elevate hepatic BA biosynthesis in the liver via suppression of FGF15 expression in ileum, indicating that less FXR is activated by BA (Miyata *et al.*, 2009). Previous research has revealed that compared with GF mice, conventionally raised (CONV-R) mice had decreased T- β -MCA and elevated T-CA. Re-derivation of *Fxr*^{-/-} mice as GF proved that intestinal microbes can induce the expression of SHP and FGF15 in a FXR-dependent mechanism (Sayin *et al.*, 2013). Furthermore, MCAs were identified as natural FXR antagonists in this study. Therefore, they elucidated that intestinal microbes can modulate BA profiles through ameliorating the suppression of FXR in the ileum (Sayin *et al.*, 2013). Another study showed that oral probiotic elevated Firmicutes and Actinobacteria, but decreased Bacteroidetes and Proteobacteria, leading to the elevation of BA excretion in the feces and hepatic BA synthesis (Degirolamo *et al.*, 2014). In this study, Degirolamo *et al.* (2014) observed an increase of CYP7A1, and CYP8B1, and a decrease of FGF15, with no alteration of SHP or LRH-1 level. Interestingly, they found that probiotic-triggered changes in BA were restored in FXR- and FGF15-deficient mice. All these results demonstrated that probiotics contribute to BA deconjugation in the ileum, BA secretion in the feces, and BA synthesis in the liver through suppressing the FXR/FGF15 negative feedback mechanism of BA synthesis.

4.3 Transportation of BAs regulated by intestinal microbiota

FXR also has profound effects on the transportation of BAs (Fig. 2a) via regulating transporters in the EHC. For instance, BSEP can facilitate bile salts secreted into gallbladder to form bile. A study on human subjects showed that the BSEP promoter possesses a FXR binding site and FXR can trigger BSEP expression (Ananthanarayanan *et al.*, 2001). Previous studies elucidated that FGF15/19 suppresses

ASBT which modulates intestinal BA re-absorption in enterocytes and cholangiocytes (Li *et al.*, 2005; Sinha *et al.*, 2008). Moreover, AMP-treated mice have less BA in feces, more BA in portal blood, and elevated levels of ASBT in ileum (Miyata *et al.*, 2009). Interestingly, a decrease in ASBT in ileum was observed when AMP-treated mice were administered T-DCA or CA (Miyata *et al.*, 2011). FXR is also reported to be involved in the activation of IBABP (Hwang *et al.*, 2002), which facilitates bile salts passing through the ileal enterocytes. OST α/β contributes to the efflux of BA into portal blood and the OST α/β in mice possesses functional FXR and LRH elements, resulting in the regulation of BA synthesis (Frankenberg *et al.*, 2006). Moreover, NTCP, the major hepatic BA transporter, can be regulated by FXR through inducing SHP (Denson *et al.*, 2001). Recently, it has been shown that two antibiotic combinations clearly elevated the mRNA levels of several EHC transporters, including NTCP, OATP1B2, BSEP, and MRP2, but suppressed the mRNA levels of CYP8B1 (Zhang *et al.*, 2014).

4.4 Role of intestinal microbiota in host metabolism mediated by BAs

As noted above, intestinal microbiota exerts a profound influence on BA pool size and composition. In previous studies, BAs have been identified as regulatory molecules and have an important impact on the modulation of lipid, glucose, and energy metabolism. BA metabolic disturbance may lead to a variety of host metabolic diseases and related complications, such as obesity, type-2 diabetes, cirrhosis, and colon cancer (Zollner *et al.*, 2006; Nguyen and Bouscarel, 2008). Vrieze *et al.* (2014) speculated that gut microbes are capable of altering glucose metabolism via altering the BA pool and FGF19 signaling in humans. Based on this hypothesis, a decrease of Firmicutes, fecal BAs, and peripheral insulin sensitivity was observed after administration of oral vancomycin. This study demonstrated that gut microbes, especially the Firmicutes, are beneficial for BA and glucose metabolism. Joyce *et al.* (2014) revealed BSH enzymes expressed in the gut of GF or CONR mice noticeably changed plasma BAs and influenced gene-expression levels in both fat metabolism and metabolic signaling pathways. When CONR mice express higher levels of BSH enzymes, their weight gain, plasma cholesterol,

and hepatic triglycerides reduce significantly. In this study, intestinal microbes can regulate host fat metabolism via BSH enzymes. Taken together, intestinal microbiota can alter the BA pool and then profoundly affect host metabolism, which is clearly closely related to host health (Fig. 2b).

4.5 Potential relationships between intestinal microbiota and autophagy mediated by BAs

Autophagy is a highly conserved basic process which can degrade cytoplasmic constituents for cellular survival and the maintenance of cellular homeostasis upon nutritional deprivation (Deretic and Levine, 2009). It is known to be regulated by nutrient-sensing signaling pathways including the mammalian target of the rapamycin (mTOR) pathway. However, two research groups have shown that in the fed state, BA-activated FXR can modulate the autophagy gene network in the liver independent of the mTOR pathway (Lee *et al.*, 2014; Seok *et al.*, 2014). Seok *et al.* (2014) revealed that after a meal or administration of GW4064 (which is an FXR agonist), FXR is activated and hepatic autophagy is inhibited. Because FXR can generate the FXR-cAMP response element binding protein (CREB) complex and destroy the CREB-CREB regulated transcription coactivator 2 (CRTC2) complex, then suppress the transcriptional levels of *Atgs*, such as *Atg7*, *Ulk1*, and *Tfeb*. The CREB-CRTC2 complex is able to activate transcription of *Atgs* under nutritional starvation. Lee *et al.* (2014) revealed that BA-activated FXR strongly represses hepatic autophagy induced by nutrient deprivation, but in *Fxr*^{-/-} mice, autophagy is not inhibited. As is well known, autophagy can be induced to counter intestinal pathogenic infection (Joubert *et al.*, 2009), such as infection of *Salmonella* (Brumell *et al.*, 1999) and Group A *Streptococcus* (Levine *et al.*, 2011). Interestingly, some gut microbes (e.g. *Shigella flexneri*, *L. monocytogenes*, and *E. coli*) can escape autophagy (Allaoui *et al.*, 1992; Dortet *et al.*, 2011; Baxt *et al.*, 2013). Some gut microbes (e.g. *Staphylococcus aureus* and *Brucella abortus*) even can use autophagy for their survival, replication, and intercellular dissemination (Schnaith *et al.*, 2007; Starr *et al.*, 2012). In addition, intestinal microbiota can regulate BA pool size and composition and subsequently alter FXR which can regulate autophagy. Therefore, potential relationships between

intestinal microbiota and autophagy mediated by BAs may exist (Fig. 2c) and these relationships may have a profound effect in the therapy of many human diseases caused by autophagy disturbance, for instance, cancers, cardiovascular and cerebrovascular diseases, and neurodegenerative diseases.

5 Role of BAs in the interplay among intestinal microbes

Intestinal microbes can inhibit other intestinal microbes in different ways, such as competing for nutrients or intestinal epithelium receptors, and secreting bacteriocins to kill nearby microorganisms directly (Sekirov and Finlay, 2009). Interestingly, intestinal microbes can regulate BA profiles, which in turn modify intestinal microbes. For example, CDI is the primary stimulus of recurrent ulcerative colitis (Rupnik *et al.*, 2009). To produce toxins, the spore of *C. difficile* must germinate and then grow. Some primary BAs except for CDCA can efficiently stimulate *C. difficile* spore germination (Fig. 2d) (Sorg and Sonenshein, 2008; Heeg *et al.*, 2012). The germination-specific protease CspC, which can recognize BAs, has a vital role in *C. difficile* germination and further *C. difficile* infection (Francis *et al.*, 2013). However, secondary BAs such as LCAs and UDCAs can suppress *C. difficile* germination (Sorg and Sonenshein, 2010). Notably, a recent study revealed that intestinal extracts, which can efficiently stimulate *C. difficile* spore germination in the colon, have a lower content of secondary BAs. This study suggested that secondary BAs may inhibit *C. difficile* spore germination *in vivo* (Giel *et al.*, 2010).

FMT, which introduces a fecal enema from a healthy individual into the gut of a patient, can treat recurrent CDI (Borody and Khoruts, 2012). Recently, Weingarden *et al.* (2014) showed that FMT can restore the intestinal microbiota and fecal BA composition in patients with recurrent CDI. The process in which primary BAs are converted into secondary BAs is disrupted in patients with CDI. However, the normalization of gut microbial composition via FMT can correct BA metabolism, thereby developing an adverse environment for *C. difficile* spore germination (Weingarden *et al.*, 2014). Importantly, a recent study identified *C. scindens*, a resistance-associated gut

microbe which can efficiently inhibit *C. difficile* infection. It is BA 7 α -dehydroxylating bacteria that can convert primary BAs to secondary BAs. The engraftment of *C. scindens* can correct the biosynthesis of secondary BAs, thereby inhibiting CDI (Buffie et al., 2015). Taken together, some gut microbes which synthesize 7 α -hydroxysteroid dehydrogenase enzymes can indirectly inhibit *C. difficile* spore germination and growth through converting primary BAs to secondary BAs. Thus, BAs can act as mediators among gut microorganisms and play vital roles in maintaining intestinal homeostasis.

6 Perspectives

Although a great number of studies have demonstrated the complex interactions among intestinal microbes, BAs, host metabolism, and human health, only a few related pieces of research have elucidated that BAs can act as mediators in the regulation of intestinal microbiota and host metabolism. The mechanisms by which BAs affect the interaction between intestinal microbiota and host metabolism are poorly understood. At present, a large fraction of studies on BAs are carried out based on genetically modified mice models. However, the size and composition of BAs and the metabolism of BAs in mice are greatly different from BAs in human; as a consequence, most of these results are not applicable to humans. In this review, a new insight has been provided in the exploration of potential relationships between microbiota and autophagy. The investigation of microbial therapies, such as administering antibiotics, probiotics, and prebiotics, may be combined with the autophagic process. In addition, identification of unknown host factors similar to BA could deepen our understanding of the way in which one gut microbe acts on another. Importantly, these elucidations will provide new insights to alleviate gastrointestinal diseases and maintain intestinal health via altering host factors or supplementing several precise microbes.

中文概要

题目：胆汁酸与肠道微生物的对话机制及其在宿主代谢与健康中的作用

概要：胆汁酸只在肝脏中合成，并通过直接作用或间接作用抑杀肠道微生物。而肠道微生物又可以促进初级胆汁酸转化为次级胆汁酸，从而改变机体内胆汁酸的组成。初级胆汁酸和次级胆汁酸均可调控法尼酯 X 核受体（FXR）的表达，已有研究发现，FXR 在胆汁酸的合成与代谢、葡萄糖代谢、脂质代谢和肝脏自噬中发挥着重要作用。此外，胆汁酸在肠道微生物的互作中起到了重要作用。本文主要综述了胆汁酸与肠道微生物之间的互作及其在宿主代谢调控中的作用，首次探讨了胆汁酸与肠道微生物的互作可能调节自噬相关信号通路。

关键词：胆汁酸；法尼酯 X 核受体；肠道微生物；宿主代谢；自噬
